Regulation of Blood Flow in the Retinal Trilaminar Vascular Network

Tess E. Kornfield and Eric A. Newman
Department of Neuroscience, University of Minnesota, Minneapolis, Minnesota 55455

Light stimulation evokes neuronal activity in the retina, resulting in the dilation of retinal blood vessels and increased blood flow. This response, named functional hyperemia, brings oxygen and nutrients to active neurons. However, it remains unclear which vessels mediate functional hyperemia. We have characterized blood flow regulation in the rat retina in vivo by measuring changes in retinal vessel diameter and red blood cell (RBC) flux evoked by a flickering light stimulus. We found that, in first- and second-order arterioles, flicker evoked large (7.5 and 5.0%), rapid (0.73 and 0.70 s), and consistent dilations. Flicker-evoked dilations in capillaries were smaller (2.0%) and tended to have a slower onset (0.97 s), whereas dilations in venules were smaller (1.0%) and slower (1.06 s) still. The proximity of pericyte somata did not predict capillary dilation amplitude. Expression of the contractile protein α-smooth muscle actin was high in arterioles and low in capillaries. Unexpectedly, we found that blood flow in the three vascular layers was differentially regulated. Flicker stimulation evoked far larger dilations and RBC flux increases in the intermediate layer capillaries than in the superficial and deep layer capillaries (2.6 vs 0.9 and 0.7% dilation; 25.7 vs 0.8 and 11.3% RBC flux increase). These results indicate that functional hyperemia in the retina is driven primarily by active dilation of arterioles. The dilation of intermediate layer capillaries is likely mediated by active mechanisms as well. The physiological consequences of differential regulation in the three vascular layers are discussed.

Key words: blood flow; capillary; functional hyperemia; pericyte; rat; retina

Introduction

The brain has high metabolic requirements, consuming 20% of the energy of the body while constituting only 2% of its mass. Oxygen and glucose delivery to the brain is critical for maintaining proper function, and the mechanisms that regulate blood flow are both complex and essential. On a global level, the blood supply of the brain is controlled by autoregulatory mechanisms that compensate for variations in blood pressure. On a fine spatial scale, functional hyperemia regulates blood flow in response to local neuronal activity. Increased synaptic activity results in the dilation of blood vessels, increased blood flow, and reduced blood deoxyhemoglobin. The latter response is exploited to generate functional brain images using the BOLD technique. Recent work has elucidated the neurovascular coupling mechanisms underlying functional hyperemia, a quest that has implicated both the underlying functional hyperemia to brain function, it remains incompletely understood.

It is well known that arterioles regulate blood flow in the brain (Vanzetta et al., 2005; Devor et al., 2007; Boas et al., 2008). However, the role of capillaries in actively regulating blood flow remains uncertain. Active capillary dilation would deliver oxygen with much greater spatial precision than arterioles. An active capillary role is supported by work in olfactory glomeruli (Chaigneau et al., 2003) and the subventricular zone (Lacar et al., 2012). In addition, pericytes, contractile cells that surround capillaries, can regulate capillary diameter in both the retina and cortex (Schönfelder et al., 1998; Peppiatt et al., 2006; Puro, 2007; Hamilton et al., 2010), and pericytes in the somatosensory cortex dilate vessels in response to sensory stimulation (Hall et al., 2014). In contrast, another report indicates that capillaries respond passively and that active pericyte relaxation does not contribute to cortical functional hyperemia (Fernández-Klett et al., 2010).

We now address the questions of blood flow regulation and active control of blood flow by capillaries in the in vivo retina. The retina offers several advantages in studying functional hyperemia. It can be imaged non-invasively, its vasculature is easily visualized, it has a high density of capillary pericytes, and it can be stimulated physiologically with light. The retinal vasculature is a highly interconnected structure composed of three planar vascular layers at different retinal depths (Paques et al., 2003; Genevois et al., 2004; Ganesan et al., 2010; Stahl et al., 2010; Ivanova et al., 2014). To our knowledge, functional hyperemia in the three retinal vascular layers has not been described previously.

We have characterized blood flow regulation by measuring flicker-evoked changes in vessel diameter and red blood cell (RBC) flux in arterioles, capillaries, and venules in the rat retina.

BP, Mean arteriole blood pressure; n, number of rats.

Figure 1. Measurement of blood vessel diameter and RBC flux in the retina. A, Confocal image of a whole-mount retina labeled for the blood vessel marker isolectin (blue), the contractile protein α-SMA (red), and the pericyte marker NG2 (green). Blood vessel order in the superficial vascular layer is indicated. First-order arterioles (1) branch from the central retinal artery. Each subsequent branch (2-5) has a higher order. Venules (V) connect with the central retinal vein. Scale bar, 100 μm. B, In vivo confocal line-scan images of vessels in the retina, labeled by intravenous injection of FITC dextran. For line-scan images of capillaries (B1), vessel diameter is calculated as the distance between the borders of the vessel lumen (red dots). Segments in which diameter cannot be measured accurately (yellow dots) are ignored. Flux is measured by counting the passage of single RBCs (black vertical lines). In larger vessels, diameter is also measured as the distance between the borders of the vessel lumen (B2; red dots), and flux is calculated by counting the passage of fluorescently labeled RBCs, imaged at a different wavelength (B3; bright vertical lines).

We find that flicker-evoked dilations are larger and faster in arterioles than in downstream capillaries and venules. Intriguingly, we find that functional hyperemia differs dramatically in the capillaries of the three vascular layers.

Materials and Methods
In vivo preparation. The in vivo rat retinal preparation has been described previously (Srienc et al., 2012). All animals were treated in accordance with the University of Minnesota Institutional Animal Care and Use Committee guidelines. Briefly, 2- to 3-month-old male Long–Evans rats were anesthetized with isoflurane (2%), and the femoral artery and vein were cannulated for monitoring of blood pressure and injection of anesthetics and paralytics, respectively. A tracheotomy was performed. After surgery, the animal was anesthetized with α-chloralose (α-chloralose–HBC Complex; Sigma C8649; 800 mg/kg bolus and 550 mg · kg⁻¹ · h⁻¹ sustained infusion), and the paralytic gallamine trithiodide (Sigma G8134; 20 mg/kg bolus and 20 mg · kg⁻¹ · h⁻¹ sustained infusion) was administered to reduce eye movements. The paralytic agent did not affect the flicker-evoked vascular responses. A contact lens was placed over the eye. The animal was mounted in a custom stereotaxic holder that was attached to a stage, and the retina was imaged with a confocal microscope (Olympus FV1000) and a 4 × dry 0.16 numerical aperture objective. A heating blanket was used to maintain the animal’s body temperature at 37°C. The rat was ventilated (SAR-1000; CWE) with a mixture of 30% O₂ and 70% N₂ at 55 breaths/min with a tidal volume of ~3.4 ml, a 1:1 inspiration/expiration fraction, and 2 mmHg positive end-expiratory pressure. Oxygen saturation (sO₂; MouseOx; Starr Life Sciences), end-tidal CO₂ (microCapStar; CWE), and arterial blood pressure (Pressure Monitor BP-1; World Precision Instruments) were measured in real time. Carbon dioxide partial pressure (pCO₂), oxygen partial pressure (pO₂), and pH were sampled periodically (ABL800flex; Radiometer), and ventilation parameters were adjusted to maintain physiological parameters within normal limits (Table 1). Large tidal volume breaths up to 30 cmHg were given every ~5 min to maintain good lung ventilation. These breaths were often given immediately before blood sampling, accounting for the high pO₂ we observed. If physiological parameters deviated from the normal range, the retinal functional hyperemia response was reduced or absent. Data were only collected when parameters were within the normal range. After experimentation, animals were killed with an intravenous injection of potassium chloride (2 mEq/kg), and the right eye was removed for immunohistochemical labeling.

Fluorescent RBC labeling. RBCs were labeled with the lipophilic dye carbocyanine 1,1’-dioctadecyl-3,3,3’,3’-tetramethylindodicarboxyanine, 4-chlorobenzenesulfonate salt (DiD solid; Invitrogen D-7757) using a procedure modified from Unthank et al. (1993). A total of 350 μl of blood was withdrawn from the arterial line, and RBCs were isolated by adding 700 μl of blood plasma buffer (PBp; in mEq: 128 NaCl, 15 glucose, 10 HEPES, 4.2 NaHCO₃, 3 KCl, 2 MgCl₂, and 1 KH₂PO₄. pH 7.4; Khoo-
and centrifuged for 5 min at 1500 rpm. RBCs were resuspended in 1.4 ml of BPB, and the cell suspension was gently mixed into a dye solution composed of 1.4 ml of Diluent C (Sigma CGLDIL) and 35 μl of DiD (2.5 mg/ml in 100% ethanol). The solution was incubated for 5 min at 37°C with periodic inversion to ensure uniform labeling. After labeling, 700 μl of serum was added, and the solution was incubated for 1 additional minute. The fluorescent RBCs (fRBCs) were then centrifuged for 5 min at 1500 rpm and washed twice by gentle mixing in 3.5 ml of BPB containing 10% serum, followed by 5 min centrifugation at 1500 rpm to remove unbound dye. Washed and labeled cells were resuspended in BPB up to a volume of 1 ml, and 0.2-1 ml of blood solution was injected into the intravenous line to achieve the desired in vivo labeled cell density. An fRBC density of ~0.9% (of total RBCs) was used for measuring flux in large vessels, and a density of ~1.2% was used for measuring flux in capillaries.

Vessel diameter and RBC flux measurements. Fluorescein isothiocyanate (FITC) dextran (2000 kDa; 1 ml of 3% solution; Sigma FD200S) was administered intravenously to visualize the vasculature. Vessel luminal diameter and RBC flux were measured simultaneously using confocal line scans oriented perpendicular to the vessel (Fig. 1). FITC and fRBCs were imaged using 488 and 635 nm laser lines, respectively. The confocal laser illumination was maintained as low as possible to minimize photoreceptor stimulation. Control experiments demonstrated that the confocal illumination did not reduce flicker-activated vascular responses or retinal ganglion cell activity measured with extracellular electrodes. Two trial and stimulus paradigms were used for data acquisition. In the first, used for all blood vessels, the line-scan acquisition (~650 Hz) was at least 47 s in duration. However, this scan rate was too low to capture the passage of fRBCs in large vessels, and a density of ~1.2% was used for measuring flux in capillaries.

Measurement of vessel diameter and RBC flux at a specific location on a blood vessel was made between two and eight times, and these trials were averaged to create a mean, which we call a series. All analyses presented here are performed on series data. The full dataset contains 204 series from 47 rats.

Response onset time. Response onset time of a vessel was defined as the time to 20% of the peak diameter response. The peak response was calculated as the largest diameter within the first 4 s after stimulus onset, a procedure designed to isolate the first phase of the dilatory response (Fig. 3).
Table 2 and isolectin. To reveal stimulus onset was measured only for those series in which the peak response was not 4 s of the vascular tree and the intensity of the fluorophores that labeled NG2 before blocking.

Immediately after the animals were killed, the right (experimental) retina was prepared using an established whole-mount protocol (Chan-Ling, 1997). After fixation (4% paraformaldehyde for 1 h) and blocking (10% donkey serum and 1% Triton X-100 in PBS for 4–12 h), retinas were incubated for 3 d with primary antibodies for rabbit-NG2 (1:1000; Millipore AB5320) and mouse-α-SMA; 1:800; Dako M0851). Retinas were then washed and donkey anti-mouse-594 (both 1:750 and from Jackson ImmunoResearch) was applied along with collagenase/dispase (2 mg/ml in PBS for 30 min; Roche 269 638) before blocking.

Vessel diameter traces in B are normalized for comparison of onset times. D, The onset time of vessels of different order, shown as box plots, with the ± symbol indicating outliers. For details of onset time calculation, see Materials and Methods.

Figure 4. Flicker-evoked response frequency and onset time in the retinal vasculature. A, Percentage of vessels responding to flicker stimulation, defined as a response >3 SDs above baseline. B, Time course of flicker-evoked dilation of vessels in the superficial vascular layer. Note that the flicker stimulus (open bar) continues beyond the end of the traces. C, Vessel diameter traces in B are normalized for comparison of onset times. D, The onset time of vessels of different order, shown as box plots, with the ± symbol indicating outliers. For details of onset time calculation, see Materials and Methods.

A 3A shows a biphasic dilation in arterioles). The 20% onset time was measured only for those series in which the peak response was not 4 s of the vascular tree and the intensity of the fluorophores that labeled NG2 before blocking.

Immediately after the animals were killed, the right (experimental) retina was prepared using an established whole-mount protocol (Chan-Ling, 1997). After fixation (4% paraformaldehyde for 1 h) and blocking (10% donkey serum and 1% Triton X-100 in PBS for 4–12 h), retinas were incubated for 3 d with primary antibodies for rabbit-NG2 (1:1000; Millipore AB5320) and mouse-α-smooth muscle actin (α-SMA; 1:800; Dako M0851). Retinas were then washed and incubated for 2 d with the secondary antibodies donkey anti-rabbit-488 and donkey anti-mouse-594 (both 1:750 and from Jackson ImmunoResearch) and the blood vessel marker Isolectin GS-IB4-647 (1:75; Invitrogen I32450). Retinas were mounted on slides and imaged with confocal microscopy. The area of the retinal whole mount that matched the area we measured in vivo was imaged to determine vessel branch order, the strength of α-SMA expression, and the distance of each vessel to the retinal surface. Vessel diameter traces in B are normalized for comparison of onset times. D, The onset time of vessels of different order, shown as box plots, with the ± symbol indicating outliers. For details of onset time calculation, see Materials and Methods.

Vessel density in the trilaminar vascular network

We quantified the density of blood vessels in each of the three vascular layers in the rat retina. Immunohistochemically labeled images of the superficial, intermediate, and deep vascular layers were skeletonized (Fig. 2B), and the linear density of the vessels in each layer was quantified (n = 5 retinas). The vast majority of vessels analyzed were capillaries, although some second- and third-order arterioles were present in the superficial vascular layer, and draining venules were occasionally present in the deep vascular layer. The deep vascular layer had the highest linear density of the three layers (2.85 ± 0.18 µm/100 µm²; p < 0.001), whereas the superficial and intermediate vascular layer densities did not differ (1.74 ± 0.10 and 1.56 ± 0.13 µm/100 µm²; Fig. 2C). These values are very similar to those measured in adult mice (Ganesan et al., 2010, 2011) and humans (Tan et al., 2012).

The total blood volume in the three vascular layers can be estimated by multiplying the mean cross-sectional area of the blood vessels in each layer by the linear vascular density in that layer. The mean baseline diameters of arterioles, capillaries, and venules are given in Figure 3C and Table 2. We find that total blood volume in the superficial, intermediate, and deep layers is 41.3, 28.2, and 65.3 µm³/100 µm², respectively. These values are only estimates because they do not include the arterioles of the superficial layer or the draining venules of the deep layer.
Retinal vessels dilate in response to flicker stimulation

We used a 5 Hz diffuse flickering light to evoke functional hyperemia, a stimulus that is known to effectively activate neurons in the inner retina (Miller, 2001). The magnitude of flicker-evoked dilation differed according to vessel order. In the superficial vascular layer, response amplitude decreased with vessel order, with the largest dilations seen in first-order arterioles (Fig. 3A,B,D). The response profile of vessel dilation also varied according to vessel order. First-, second-, and third-order arterioles displayed a clear biphasic response (Fig. 3A), with a first peak occurring within a few seconds of light onset and a second phase developing slowly and peaking at ~13 s after light onset. Superficial capillaries and venules had more subtle biphasic response profiles. We have observed previously similar flicker-evoked biphasic increases in diameter (Mishra and Newman, 2011), Müller cell Ca\(^{2+}\) signaling (Newman, 2005), and blood velocity (Srienc et al., 2010) in the rat. In contrast, biphasic responses have not been observed in the cat (Buerk et al., 1995) and human (Polak et al., 2002; Garhöfer et al., 2003) retinas. When we quantified dilation as the percentage increase in diameter during the first 4 s after light onset (capturing the first peak), we found that dilations in the first-order arterioles were larger than in third-order arterioles and all other downstream vessels (p < 0.001; Fig. 3D, Table 2).

The second-order arteriole dilations were larger than superficial capillaries and venules (p < 0.01).

We then compared the dilatory responses of capillaries in the three vascular layers. Unexpectedly, we found dramatic differences in flicker-evoked capillary dilation in the three layers (Fig. 3E–G). The time courses of flicker-evoked capillary dilation were strikingly different. Dilation of superficial layer capillaries resembled the biphasic dilatory response of upstream arterioles, whereas dilation of deep layer capillaries resembled the downstream venule response. In contrast, the slow, continuously increasing dilation of intermediate layer capillaries resembled neither the responses of superficial or deep layer capillaries nor the responses of arterioles or venules. To quantify the capillary responses in the three vascular layers, we calculated the mean dilation during the entire 15 s stimulus. Intermediate layer capillaries dilated more than twice as much as superficial and deep layer capillaries (2.55 ± 0.30 vs 0.89 ± 0.16 and 0.66 ± 0.28%; p < 0.001; Fig. 3G). In summary, we find that arterioles dilate more than other retinal vessels and likely drive blood flow in the retinal vasculature. Furthermore, the large, slow dilations of capillaries in the intermediate vascular layer suggest the presence of a unique regulatory mechanism.

Arterioles respond rapidly and consistently to flicker stimulation

The location within the vascular network in which functional hyperemia is initiated remains an open question. In the brain, evidence suggests that blood flow first increases in the middle cortical layers before spreading toward the pial surface (Silva and Koretsky, 2002; Tian et al., 2010; Lindvere et al., 2013), although it remains to be determined which vessels are responsible for the initial increase (Hall et al., 2014). We found that, in the retina, arterioles dilate more reliably and faster than downstream capillaries and venules. We first calculated the fraction of vessels that dilated in response to a flicker stimulus. Vessels were considered to respond if their diameter during the stimulus rose at least 3 SDs above baseline. First-order arterioles responded 100% of the time (n = 7). The likelihood of vessel dilation tended to decrease with distance along the vascular tree (Fig. 4A, Table 2). The percentage of vessels responding was 92% (n = 12) for second-order arterioles and fell to as low as 61% (n = 18) for capillaries in the deep vascular layer. Deviating from this trend, 93% (n = 29) of capillaries in the intermediate layer and 100% (n = 5) of venules dilated.

We calculated the time at which vessels began to dilate, the onset time, to determine which vessels responded first to flicker stimulation. We first estimated the onset time by examining the average response profile for each type of vessel (Fig. 4B). When these traces were normalized to the peak response (Fig. 4C), we observed that first- and second-order arterioles dilate most rapidly. Venules had a noticeable delay in their rising phase. A more quantitative assessment was obtained by defining onset as the time it takes for a vessel to reach 20% of its peak dilation (Fig. 4D). There was a general trend for onset time to be shortest for first-, second-, and third-order arterioles (0.73 ± 0.08, 0.70 ± 0.16, and 0.60 ± 0.34 s, n = 7, 11, and 23, respectively) and longer for superficial capillaries (0.97 ± 0.49 s, n = 46). Venules had the longest onset time (1.06 ± 0.49 s, n = 5). However, none of these groups were significantly different from each other.

RBC flux increases in response to flicker stimulation

RBC flux is a direct and sensitive measure of blood flow. If functional hyperemia is controlled solely by the active dilation of retinal arterioles, then the flicker-evoked RBC flux increase in all downstream vessels should be equal. However, this was not what we observed. RBC flux in first-order arterioles and venules, measured using ultrafast line scans with a 2 s flicker stimulus, increased to a peak value of 11% and had nearly identical time courses (Fig. 5A). RBC flux in smaller vessels was measured with standard line scans and a 15 s flicker stimulus. Although the initial flicker-evoked flux increase was equal in second- and third-order arterioles and superficial capillaries, flux changes during the second phase of the response decreased with vessel order (Fig. 5B). We calculated the mean flicker-evoked RBC flux change in superficial layer vessels during the first 2 s of the stimulus. Restricting our analysis to the first 2 s allowed us to include short trials in which only a 2 s stimulus was used. Light-evoked flux increases averaged 4.67 ± 1.71% (n = 8) in first-order arterioles, 8.19 ± 0.71% (n = 5) in second-order arterioles, 6.74 ± 0.75% (n = 6) in third-order arterioles, 11.33 ± 1.47% (n = 32) in capillaries, and 3.94 ± 1.71% (n = 8) in venules (Fig. 5C,D).

Vessel orders 1, 2, and 3 are the first, second, and third branches off the central retinal artery. D, Deep layer capillaries; I, intermediate layer capillaries; S, superficial layer vessels of order 4 and higher, defined as capillaries; V, venules are the first branch off the central retinal vein. Dilation indicates mean dilation during the first 4 s after stimulus, and % responding indicates the percentage of series that showed stimulus-evoked dilations that rose at least 3 SDs above baseline.
These flux increases were not significantly different from each other.

We then characterized flux in the capillaries of the three vascular layers. Baseline flux in superficial, intermediate, and deep vascular layers did not differ (61.0 ± 5.3, 42.2 ± 3.2, and 39.4 ± 3.2 RBCs/s, n = 32, 18, and 12, respectively; Fig. 5G). However, flicker-evoked flux increases were dramatically different (Fig. 5E,F,H). When averaged over the 15 s stimulus period, the flux increase in the intermediate vascular layer was much greater than the increases in the superficial and deep layers (25.65 ± 5.16 vs 0.82 ± 2.17 and 11.27 ± 2.85%; p < 0.001 and p < 0.05, respectively; Fig. 5H).

The time course of flicker-evoked capillary flux changes also differed in the three vascular layers (Fig. 5E). After an initial peak, flux in intermediate capillaries continued to rise throughout the stimulus period, similar to the intermediate layer dilatory response (Fig. 3E). The time course of the flux increase in the deep capillaries also paralleled the dilation in vessels of the deep vascular layer. However, the flux change in superficial layer capillaries did not match the dilatory response. This was particularly evident at the end of the 15 s stimulus period. At this time, flux had increased by 34% in the intermediate vascular layer and 10% in the deep capillary layer. Strikingly, flux had actually decreased by 7% in the superficial capillaries. Because the superficial capillaries remained dilated for the duration of the stimulus, the decrease in flux must reflect a decrease in perfusion pressure in these vessels. This is likely attributable to the diversion of flow to the intermediate and deep layer capillaries.

Pericyte proximity does not predict dilation amplitude

Active regulation of blood flow in capillaries remains a controversial issue (Fernández-Klett et al., 2010; Hall et al., 2014). Active regulation in capillaries would occur via pericytes, because they are the only contractile cells associated with these vessels. We tested whether pericytes in the retina actively regulate blood flow by measuring flicker-evoked capillary dilation as a function of distance from pericyte soma. If pericytes actively regulate blood flow, we would expect flicker-evoked dilation to be greater near pericyte soma, where the circumferential pericyte processes are located, rather than farther away (Nehls and Drenckhahn, 1991; Peppiatt et al., 2006; Kotecki et al., 2010; Dore-Duffy and Cleary, 2011).

We measured flicker-evoked capillary dilation at different sites along capillaries in the three vascular layers. After in vivo experimentation, retinas were removed and labeled for the chondroitin sulfate proteoglycan NG2 to localize pericyte soma, which appeared as protrusions from the capillary wall (Fig. 6A, arrowheads). In vivo and whole-mount images of the same retinal regions were aligned,
either all capillaries were pooled together or each layer was considered separately (Fig. 6D). These results are discussed below in the context of our other findings.

α-SMA expression reflects vascular responsiveness

α-SMA is a contractile protein expressed in pericytes and in the vascular smooth muscle cells that surround arteries and arterioles. Its level of expression has been correlated with the degree of vascular contractility in rat and mouse (Schildmeyer et al., 2000; Hinz et al., 2001; Tomasek et al., 2006). Other reports indicate that a subset of capillary pericytes express α-SMA (Nehls and Drenckhahn, 1991; Bandopadhyay et al., 2001), but we could not resolve α-SMA labeling to the level of individual pericytes. Instead, we categorized each vessel segment that was investigated in vivo as expressing high, medium, or low levels of α-SMA. In agreement with previously published work (Nehls and Drenckhahn, 1991; Hughes and Chan-Ling, 2004), we found that α-SMA expression decreased with increasing vessel order (Fig. 7) and was often undetectable in the smallest capillaries (Fig. 7B, arrowheads). α-SMA expression levels were lower in the intermediate and deep vascular layers than in the superficial vessels (Fig. 7C), although this may have been attributable to reduced antibody penetration. In our initial studies using a standard immunohistochemistry protocol, α-SMA expression was unexpectedly low in most regions of first-order arterioles compared with second-order arterioles. Collagenase/dispase digestion of the retina before performing immunohistochemistry increased antibody penetration, and we observed more regions of high α-SMA labeling in the first-order arterioles (Fig. 7B, arrows). Enzyme digestion did not disrupt the binding of other antibodies, nor did it change the observation that α-SMA expression decreases with vessel order.

Discussion

Active dilation of arterioles drives functional hyperemia in the retina

We have found that flickering light evokes large, rapid, and consistent dilations in retinal arterioles but smaller, slower, and inconsistent dilations in downstream capillaries and venules. Retinal arterioles are also highly enriched with α-SMA, a protein whose expression levels correlate with contractility (Schildmeyer et al., 2000; Hinz et al., 2001; Tomasek et al., 2006). Together, these results indicate that functional hyperemia in the retina is driven principally by the active dilation of arterioles. Although the initial transient dilation in downstream capillaries and venules is likely attributable to passive stretch, we propose that more complex regulatory mechanisms are at play during prolonged stimulation. These mechanisms, discussed below, can account for the differential blood flow responses we observed in the three vascular layers.

Flicker stimulation evoked small dilations in venules compared with arterioles in our experiments. In the human retina, in contrast, venule and arteriole dilations are of similar magnitude (Polak et al., 2002; Garhofer et al., 2004; Hammer et al., 2011; Noonan et al., 2013). The difference could arise because venule diameters are only ~21% larger than arteriole diameters in humans but 41% larger in our rats. Thus, human venules may need to dilate more than rat venules to accommodate the same increase in blood flow.

Baseline blood flow in the three vascular layers

The intermediate vascular layer vessels had the smallest total blood vessel volume and approximately the same baseline flux as the other two vascular layers, indicating that total baseline blood flow was lower in the intermediate layer than in the other two vascular layers. This is consistent with intraretinal PO2 measurements, which reveal high PO2 near the surface of the rat retina and in the region near the deep vascular layer and lower PO2 in the region near the intermediate vascular layer (Lau and Linsenmeier, 2012). Although intermediate layer blood flow is low at baseline, it is likely adequate to support the metabolic needs of the inner retina during constant dim illumination (Miller, 2001).

Differential regulation of blood flow in the three vascular layers

We observed a striking difference in flicker-evoked regulation of capillary blood flow in the three vascular layers of the retina. Stimulation evoked much larger dilations in intermediate layer capillaries than in capillaries of the superficial and deep vascular layers. At the end of the 15 s stimulus, intermediate layer capillaries had diluted 4.4%. According to a modified version of the Hagen-Poiseuille law (Blinder et al., 2013), which accounts for vessel diameter, as well as the effects of hematocrit and RBC interactions with the vessel wall, a 4.4% dilation translates to a 16.5% decrease in vascular resistance. In comparison, the resistance decrease in the superficial and deep layer capillaries was 3.9 and 3.3%.

The intermediate layer capillary dilation had a unique time course, increasing continually for the duration of the stimulus. Dilation of the superficial and deep layer capillaries, in contrast, remained relatively constant throughout the stimulus. Flicker-evoked RBC flux in the intermediate vascular layer continued to rise for the duration of the stimulus, mirroring the dilation observed in intermediate layer capillaries. Averaged over the duration of the stimulus, the intermediate layer flux increase was more
than twice that in the deep capillary layer. In contrast, after a transient increase, flux in the superficial layer capillaries declined steadily during stimulation. Third-order arterioles in the superficial vascular layer showed a similar slow flux decline. The flux decrease in the superficial layer vessels is likely attributable to a “steal” effect (Raichle, 1998), with blood being diverted to the intermediate and deep layer capillaries.

The differential regulation of blood flow in the three vascular layers will affect oxygen and nutrient delivery and may reflect differences in neuronal metabolic demand. The intermediate vascular layer supplies neuronal somata and synapses of the inner retina, which are activated more by changes in luminance than by steady illumination (Miller, 2001). Stimulus-evoked activity results in large increases in neuronal metabolism in this layer (Bill and Sperber, 1990; Lau and Linsenmeier, 2012). The larger flicker-evoked blood flow increase in intermediate layer capillaries may be necessary to meet the increased metabolism of these neurons. In contrast, the deep vascular layer supplies oxygen and nutrients to the synapses in the outer plexiform layer, which are active under all stimulus conditions. Therefore, there is little metabolic need for large increases in blood flow to the deep vascular layer. The superficial capillary layer primarily supplies the retinal ganglion cells, which are activated by changes in light (Miller, 2001). However, oxygen is supplied to this layer by both the superficial layer vessels and by the vitreous humor, in which pO2 is higher farther away could be false. This possibility is supported by recent observations in the cortex (Hall et al., 2014), where capillary dilations at pericyte somata and processes were equal but were smaller where pericytes were absent. In the retina, where pericyte density is higher than in the cortex (Frank et al., 1987), it is difficult to find regions where pericytes are absent. Given that we used a diffuse stimulus to activate the retina, that retinal pericytes are closely spaced, and that they are electrically coupled (Puro, 2007), it is not surprising that all regions of capillaries with pericyte coverage dilate to a similar extent. Second, we did not characterize flicker-evoked dilation in the diving capillaries connecting superficial layer vessels to intermediate and deep layer capillaries. It is possible that pericyte-mediated dilations are present in these vessels. Third, although α-SMA expression in the intermediate and deep layer capillaries is low, capillary pericytes may express enough actin to mediate active responses. The low levels of α-SMA expression we observed in the intermediate layer capillaries may express enough actin to mediate active responses.

Our observations on blood flow in the trilaminar retinal network correspond well with investigations in the cortex. Although the cortex is a stratified tissue, there are no discrete cortical vascular layers as there are in the retina. Nevertheless, fMRI (Smirnakis et al., 2007; Kim and Kim, 2010; Goense et al., 2012), two-photon imaging (Lindvere et al., 2013), laser Doppler flowmetry (Norup Nielsen and Lauritzen, 2001), and autoradiography (Gerrits et al., 2000) studies indicate that sensory stimulation results in greater increases in blood flow in the middle cortical layers, including layer IV, where neuronal and vascular density
These slow volume increases have been attributed to the windkessel effect, which in active arteriolar dilation results in a pressure increase that passively dilates downstream vessels (Mandeville et al., 1999; Kong et al., 2004; Huppert et al., 2007; Drew et al., 2011; Barrett et al., 2012). The windkessel effect does not, in itself, account for differential dilation of the three capillary layers. Several other factors could contribute to differential dilation. First, intermediate layer capillaries, which have a smaller total volume than capillaries in the other two layers, would also have a higher resistance. Dilation of upstream arterioles would generate greater pressure increases in intermediate layer capillaries, leading to larger passive stretch. Second, capillaries in the intermediate layer could have a higher compliance, resulting in greater stretch for a given pressure increase.

Conclusions

Our results indicate that arterioles are primarily responsible for generating functional hyperemia in the retina. These vessels display large, rapid, and consistent flicker-evoked dilations and high α-SMA expression. We also found that blood flow through the three vascular layers in the retina is differentially regulated. Prolonged flicker stimulation evokes a large, slowly developing dilation and an increase in flow in intermediate layer capillaries that are not observed in the other two vascular layers. Active capillary dilation likely contributes to this response.
