Edited by Per O. Andersen, University of Oslo, Oslo, Norway, and approved October 1, 2003 (received for review February 24, 2003)

Repetitive correlated activation of pre- and postsynaptic neurons induced long-term potentiation (LTP) of synaptic transmission among hippocampal neurons grown on a layer of astrocytes (mixed cultures) but not among neurons cultured in glial conditioned medium. Supplement of D-serine, an agonist for the glycine-binding site of N-methyl-D-aspartate (NMDA) receptors, enhanced NMDA receptor activation and enabled LTP induction in glial conditioned medium cultures. The induction of LTP in both mixed cultures and hippocampal slices was suppressed by NMDA receptor antagonists, glycine-binding-site blockers of NMDA receptors, or an enzyme that degrades endogenous D-serine. By providing extracellular D-serine that facilitates activation of NMDA receptors, astrocytes thus play a key role in long-term synaptic plasticity.

Astrocytes, the most abundant glial cells in the brain, are found to associate closely with neuronal synapses (1, 2). Although astrocytes lack excitability in terms of action potentials, they express various neurotransmitter receptors and ion channels and can create Ca2+ waves in response to various stimuli, including neuronal activity. Furthermore, astrocytes can secrete many factors that modulate neuronal activity (3–5). Recent studies have shown that astrocytes play important roles in neurogenesis (6), synaptogenesis (7, 8), and synaptic modulation (3–5, 9–11). There is evidence that astrocytes may also contribute to high-level brain functions such as motivation, learning, and behavior (12). Given the potential role of glial factors in neuronal functions, it is of interest to know whether and how astrocytes may contribute to the induction of long-term potentiation (LTP), the most extensively studied form of synaptic plasticity that may serve as a cellular mechanism underlying learning and memory (13, 14). Deletion of glial fibrillary acidic protein (GFAP) or S-100B in the mouse (15, 16) resulted in an enhancement of LTP, but how these cytoplasmic proteins in glial cells affect synaptic plasticity remains unknown. Studies of LTP are usually carried out in slice preparations, in which glial cells are intimately associated with neurons and synapses. It is thus difficult to separate the role of glia in synaptogenesis from a direct modulatory role of glial factors in synaptic plasticity. To address this problem, we have established in the present study two types of hippocampal neuronal cultures: conventional mixed cultures, in which neurons were grown on a layer of astrocytes, and cultures in which the neurons were fed with glial conditioned medium (GCM) but grown without contacting astrocytes (see Materials and Methods). In the latter GCM cultures, apparently normal synaptogenesis occurs among hippocampal neurons. By using correlated stimulation of pre- and postsynaptic neurons to induce LTP (17), we were able to analyze directly the role of immediate astrocyte-derived factors in the induction of LTP. We found that LTP could be induced in mixed cultures, but not in GCM cultures, and that glia-derived D-serine plays a key role in LTP induction by its action on the N-methyl-D-aspartate (NMDA) subtype of the glutamate receptors. Furthermore, we showed that in hippocampal slices, the induction of LTP at Schäffer collateral–CA1 pyramidal cell synapses also critically depends on the presence of intact glial cells and extracellular D-serine. Taken together, we have identified an astrocyte-derived factor that contributes to activity-induced long-term synaptic plasticity.

Materials and Methods

Cell Cultures. Primary cultures of astrocytes were prepared as described (18, 19) with some modifications. In brief, cortices were prepared from 1-d-old rat and were dissociated by trypsin, plated on polyD-lysine-coated glass coverslips, cultured with Eagle’s MEM (GIBCO) containing 10% FBS, and maintained at 37°C in a 5% CO2 incubator. Astrocytes formed a confluent layer 10–14 d after plating and were ready for mixed cultures and GCM cultures (see below). Three types of hippocampal neuronal cultures were prepared in the present study: (i) pure neuronal cultures, as described (8, 20), with some modifications. Hippocampi from embryonic day 18 rat were dissociated by trypsin treatment, plated on polyD-lysine-coated glass coverslips at a cell density of 60,000/ml and maintained in MEM containing 20% glucose, 2 mM glutamine, 1% BSA, and 10% FBS for 24 h. These cultures were then treated with cytosine arabinoside (10 μM) for 48 h to kill proliferating cells and subsequently maintained in Neurobasal medium (GIBCO) containing 20% glucose and 2% B27 supplements. (ii) GCM cultures, prepared and cultured in the same manner as pure neuronal cultures except that, after cytosine arabinoside treatment, one coverslip prepared for pure neuronal cultures and three coverslips plated confluent with astrocyte cultures (10–14 d) were cultured side-by-side in a single 35-mm dish. This allows neurons to grow in GCM, and electrophysiological studies can be performed in the absence of astrocytes and in the recording medium. (iii) Mixed culture, prepared in the same manner as pure neuronal cultures except that neurons were plated on a layer of primary astrocytes (10–14 d) rather than directly on polyD-lysine-coated glass coverslips. The absence of glial cells in GCM cultures were confirmed by immunostaining by using antibodies for neuron-specific marker MAP2 and astrocyte marker GFAP. In mixed cultures, neurons were found to grow on top of a layer of astrocytes (Fig. 1A), whereas in GCM cultures, no astrocyte was found to be associated with the neuron (Fig. 1B). Astrocytes are easily distinguished from neurons by their morphological characteristics under phase-contrast microscopy, thus GCM cultures contaminated with astrocytes were not used for electrophysiological studies. The use and care of animals in this study follow the guidelines of the Shanghai Institutes of Biological Sciences Animal Research Advisory Committee.

Immunostaining. Cell cultures prepared as described above were fixed in 4% paraformaldehyde for 10 min before treated with blocking solution containing 10% BSA and 0.1% Triton X-100 for

Correlated pre- and postsynaptic activation induced LTP in mixed cultures (D). Correlated pre- and postsynaptic activation induced LTP in mixed cultures (D). Correlated pre- and postsynaptic activation induced LTP in mixed cultures (D).

Fig. 1. Comparing synaptic potentiation induced by correlated pre- and postsynaptic activities in two different culture preparations. (A and B) Immunostaining with anti-MAP2 (neuronal marker, red) and anti-GFAP (astrocyte marker, green) showing images of mixed (A) and GCM (B) cultures, respectively. (C and D) Correlated pre- and postsynaptic activation induced LTP in mixed cultures (C) but not in GCM cultures (D). (Upper) Phase-contrast images showing dual patch recordings from neurons in mixed (Left) and GCM (Right) cultures. The amplitude of EPSCs was normalized by the mean amplitude observed during the control period (t = −10 to 0 min). Data represent averages from all experiments (n = 10 and 9 for C and D, respectively). Arrows mark the time of repetitive correlated activation (1 Hz, 80 sec), with presynaptic stimulation (1 ms, +100 mV) preceded postsynaptic stimulation (1 ms, 2 nA) by 5 ms. Traces depict samples of averaged EPSCs from one experiment during the control period (I) and at 20–30 min after correlated stimulation (II). (Scales, 20 μm for photo images; 200 pA and 20 ms for recording traces.)

1 h at room temperature. Cultures were then stained with anti-GFAP antibody (1:1,000, Chemicon) and anti-MAP2 antibody (1:100, Santa Cruz Biotechnology) overnight at 4°C. After washing to remove excess primary antibodies, the cultures were incubated for 1 h at room temperature with fluorescence-conjugated secondary antibodies (Jackson ImmunoResearch): anti-goat-IgG-Cy5 for the MAP2 antibody, and anti-rabbit-IgG-FITC for the GFAP antibody. Excess antibody was removed, and cells were imaged by using a Zeiss LSM 510 confocal microscope.

Glial Plasmalemmal Vesicle (GPV) and Synaptosome Preparation and D-Serine Measurements. Glial and nerve ending fractions were acutely isolated by discontinuous Percoll gradient centrifugation as described (21, 22) with minor modifications. D-serine was measured acutely isolated by discontinuous Percoll gradient centrifugation as described (21, 22) with minor modifications. D-serine was measured acutely isolated by discontinuous Percoll gradient centrifugation as described (21, 22) with minor modifications.

Electrophysiology. For cultured neurons, whole-cell perforated patch recordings from two hippocampal neurons were performed simultaneously, by using amphoterin B (Sigma) for perforation (17). The patch electrodes were made from borosilicate glass capillaries (Sutter Instruments, Novato, CA), with a resistance in the range of 3–5 MΩ. The pipettes were tip-filled with internal solution and then back-filled with internal solution containing 150 ng/ml amphoterin B. The internal solution contained (in mM): 136.5 K-gluc, 17.5 KCl, 9 NaCl, 1 MgCl2, 10 Hepes, and 0.2 EGTA (pH 7.2). The recording medium was a Hepes-buffered saline containing (in mM): 145 NaCl, 3 KCl, 10 Hepes, 3 CaCl2, 8 glucose, and 2 MgCl2 (pH 7.3). The bath was constantly perfused with fresh recording medium at a slow rate (~1 ml/min) throughout the recording. All experiments were done at room temperature (20 ± 24°C). Neurons were visualized with a phase-contrast inverted microscope (IX50, Olympus). Recordings were made with two patch-clamp amplifiers (Axopatch 200B; Axon Instruments, Foster City, CA). For assaying synaptic connectivity, each neuron was stimulated at a low frequency (0.0167 Hz) by 1-ms-step depolarization from −70 to +30 mV in voltage-clamp mode, and the responses of the other neuron as well as autaptic responses in the stimulated neuron itself were recorded. The inhibitory postsynaptic currents had distinctly longer decay times and more negative reversal potentials than excitatory postsynaptic currents (EPSCs) and were sensitive to blockade by bicuculline. Only glutamatergic synapses on postsynaptic glutamatergic neurons were studied for LTP induction. LTP was induced by repetitive correlated pre- and postsynaptic activation (1 Hz, 80 sec), with presynaptic stimulation (1 ms, +100 mV) preceded postsynaptic stimulation (1 ms, 2 nA) by 5 ms (17, 26). During correlated stimulation, presynaptic neuron was voltage-clamped at −70 mV, whereas the postsynaptic neuron was current-clamped at −70 mV to allow generation of back-propagating spikes. In experiments when the ratio NMDA receptor (NMDAR)/α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPAR) was calculated, EPSCs or miniature EPSCs (mEPSCs) with both NMDAR and AMPAR components were recorded in Mg2+-free extracellular medium. The NMDAR and AMPAR components were separated temporally by their distinct kinetics (27, 28). The amplitude of NMDAR-mediated current was determined in a window between 15 and 25 ms after the peak of AMPAR-mediated component, which has a fast rising time <1 ms (27, 28).

For recordings from hippocampal slices, all experiments were carried out in the presence of GABA_A antagonist picrotoxin (50 μM). Whole-cell patch recordings were made from pyramidal neurons in the cell body layer of CA1. Recording pipettes were routinely filled with a solution containing (in mM): 125 Kgluc, 15 KCl, 8 NaCl, 4 Mg-ATP, 0.3 Na-GTP, 10 Na_2-phosphocreatine, 2 EGTA (pH 7.30). EPSPs with amplitudes in the range of 5–7 mV were induced by constant current pulses (1–5 μA, 200 μs, 0.033 Hz) through extracellular bipolar electrodes (MCE-100, RMI, Woodland Hill, CA). The membrane potential was maintained at a level of −70 mV by injection of a constant current (~60 pA). LTP was induced by 6-burst stimulation (TBS) protocol as described (29), with some modifications. A train of subthreshold synaptic stimulation consisted of five bursts of synaptic stimuli at 5 Hz given through the extracellular electrode. Each burst was composed of five pulses (0.2 ms, 1–5 μA) at 100 Hz, and the train was repeated twice with a 20-s interval. Each burst was...
results from all experiments, including data shown in A–C. Other experiments include treatments with NMDAR antagonist APV (25 μM), glycine-binding site antagonist 7-CLKY (10 μM), glycine-binding site agonist D-serine (10 μM), and heat-inactivated DAAO (0.1 units/ml; heated at 90°C for 5 min). The enhancement of EPSCs was measured by the mean amplitude of EPSCs at 20–30 min after correlated stimulation, normalized in each neuron by the mean EPSC amplitude observed during the control period (−10 to 0 min). The number associated with each column refers to the number of neurons tested in each condition. Asterisks indicate significant difference from the control group (not treated with any drug, P < 0.001, t test).

Dependence of LTP induction in mixed cultures on NMDAR activation, the glycine-binding site, and D-serine. (A–C) LTP induction in mixed cultures in the presence of glycine-binding site antagonist DCKA (10 μM, A), D-serine-degrading enzyme DAAO (0.1 units/ml, B), and D-serine (10 μM) in addition to DAAO (0.1 units/ml, C). Data were normalized in the same manner as that shown in Fig. 1C. (D) Summary of results from all experiments, including data shown in A–C. Other experiments include treatments with NMDAR antagonist APV (25 μM), glycine-binding site antagonist 7-CLKY (10 μM), glycine-binding site agonist D-serine (10 μM), and heat-inactivated DAAO (0.1 units/ml; heated at 90°C for 5 min). Endogenous D-Serine Is Critical for LTP Induction in Cultured Neurons. Consistent with previous reports (17, 30), we found that activation of NMDARs is required for the induction of LTP by correlated preand postsynaptic activity, because bath application of the NMDAR antagonist 2-amino-5-phosphonovalerate (APV, 25 μM) completely abolished LTP (Fig. 2D). Furthermore, application of 5,7-dichlorokynurenic acid (DCKA) and 7-chlorokynurenic acid, the antagonists for the glycine-binding site of NMDARs (31), also blocked LTP induction in mixed cultures (Fig. 2 A and D), indicating that LTP induction requires coactivation of the glycine-binding site of NMDARs (32). Because D-serine, an agonist for the glycine-binding site of NMDARs (31), is known to be synthesized mainly in astrocytes (23, 33–37), we tested whether the failure of LTP induction in GCM cultures (Fig. 3A) was due to the lack of D-serine that is normally supplied by astrocytes. As shown in Fig. 3 B and D, addition of D-serine (10 μM) to the culture indeed enabled the induction of LTP in GCM cultures, whereas t-serine had no effect. Furthermore, the effect of D-serine can be blocked by NMDAR antagonist APV (Fig. 3 C and D). The LTP induced in GCM cultures supplemented with D-serine appeared to be less robust than that induced in mixed cultures (comparing Figs. 1C and 3B), suggesting either a reduced capacity for LTP in neurons grown in these GCM cultures or the need of other astrocyte factors for LTP induction in addition to D-serine. The requirement of endogenous D-serine for the induction of LTP in mixed cultures was further confirmed by the effect of D-serine-degrading enzyme DAAO (34, 38). Incubation of mixed cultures with DAAO (0.1

For recording of cultured neurons or slices, data were accepted for analysis only when postsynaptic currents or voltages did not vary beyond 15% of the average values during the control period, and the input resistance (100–300 MΩ) remained constant throughout the experiment. Signals filtered with amplifier circuitry were sampled at 10 kHz and analyzed by using CLAMPPEX 8.0 (Axon). Analysis of mEPSCs was performed with Mini Analysis Program, Ver. 5.2.5 (Synaptosoft, Decatur, GA). Data were presented as means ± SEM, and statistical differences were determined by Student’s t test. Reagents were obtained from Sigma–Aldrich, except where noted.

Results

**Correlated Activity Induced LTP in Mixed Cultures but Not in GCM Cultures.** Dual perforated whole-cell recording was made from synaptically connected pairs of hippocampal neurons in mixed or GCM cultures (Fig. 1 C and D), and repetitive correlated stimulation was applied to the pre- and postsynaptic neurons to induce LTP (17). Neurons in mixed cultures were in contact with a layer of astrocytes, whereas those in GCM cultures were not in contact with any glial cells (see Materials and Methods). Normal recording solution was used to replace culture medium during the experiment. As shown in Fig. 1C, the amplitude of EPSCs in mixed cultures was significantly elevated after a brief period of correlated activity, during which the presynaptic neuron was stimulated repetitively 5 ms before each postsynaptic spike was initiated (1 Hz, 80 s). In contrast, when the same protocol was applied to neurons in GCM cultures, we observed no significant increase in the amplitude of EPSCs (Fig. 1D). Because no astrocytes were present in GCM cultures and no glial factors were present in the recording medium, this result suggests that astrocytes provide some immediate and essential factor(s) for the induction of LTP.
units/ml) for 30 min significantly diminished the induction of LTP in these neurons, whereas heat-inactivated DAAO had no effect (Fig. 2 B and D). Finally, application of exogenous D-serine (10 μM) during the induction period restored the capacity for LTP induction in DAAO-treated mixed cultures (Fig. 2 C and D), indicating that the enzyme DAAO did not produce nonspecific deleterious effects on the neuron that prevented LTP induction, and that excess D-serine can override the action of DAAO on the available D-serine for LTP induction.

Endogenous D-Serine Is Required for NMDAR Activation in Cultured Neurons. Glia-derived factors are known to be important for synaptogenesis (7, 8). In the present study, we found that the frequency of mEPSCs in the presence of tetrodotoxin (1 μM) and bicuculline (10 μM) and in the absence of Mg2+ was not significantly different between mixed cultures and GCM cultures, whereas very few mEPSCs were recorded in neurons cultured without astrocytes or GCM (“pure” neuronal cultures; see Materials and Methods; Fig. 4A and B). These findings suggest that synaptogenesis was similar in mixed and GCM cultures but was defective in pure neuronal cultures. We noted that the mean amplitude of mEPSCs in GCM cultures was lower than that recorded in mixed cultures (Fig. 4C). This reduced amplitude of mEPSCs may be attributed to the reduced NMDAR activation in the absence of endogenous agonist for the glycine-binding site, as suggested by the following study of the effects of D-serine on NMDA component of EPSCs in these cultures.

Previous studies have shown that glycine or D-serine is necessary for NMDAR activation (31). A slow current component of EPSCs, with characteristics of the current mediated by NMDARs and sensitive to APV or DCKA, was frequently recorded in cultured mixed neurons but not in GCM cultures (Fig. 5A). Treatment with DCKA significantly reduced the amplitude of EPSCs in GCM cultures to 75.0 ± 11.3% (SEM, n = 12) but did not affect the amplitude of EPSCs in GCM cultures (96.6 ± 7.5%, n = 11). The NMDAR- and non-NMDA- or AMPAR-mediated EPSCs can be separated temporally according to their kinetics. The current amplitude ratio of NMDAR and AMPAR components was then determined (see Materials and Methods; ref. 28). We found that the ratio in mixed cultures (0.29 ± 0.01, n = 9) was >3-fold higher than that in GCM cultures (0.08 ± 0.03, n = 7, Fig. 5C). These results indicate that in GCM cultures, NMDARs were not significantly activated during synaptic transmission. As shown in Fig. 5A and C, a supplement with D-serine (10 μM) significantly increased the slow component of EPSCs in GCM cultures but had much less effect on EPSCs recorded in mixed cultures. Thus, the lack of NMDAR activation during synaptic transmission in GCM cultures was due to a deficiency in the agonist for the glycine-binding site rather than in NMDAR expression. To test whether endogenous D-serine is responsible for the activation of NMDARs in mixed cultures, we recorded mEPSCs in mixed cultures with or without a 15-min pretreatment of DAAO (0.1 units/ml). We found that the ratio NMDAR/AMPA for mEPSCs was decreased significantly after DAAO pretreatment (Fig. 5B and D).

D-Serine Release from Cultured Astrocytes. To examine directly whether astrocytes are the main source of D-serine in our culture system, we measured the D-serine level in the culture supernatant and cell lysates by using chemiluminescence assay and/or HPLC. The results obtained with the chemiluminescence assay were similar to those obtained with HPLC (Fig. 6A). We detected a significant level of D-serine in the culture supernatant and cell lysates from pure astrocyte cultures and mixed cultures, but not from GCM cultures.

PNAS | December 9, 2003 | vol. 100 | no. 25 | 15197
Furthermore, bath application of glutamate to mimic neuronal activity was assayed by chemiluminescence. As reported, the induction of LTP by TBS depends on the presence of L-serine (23). We found that medium from mixed cultures, the same treatment had no effect on D-serine level (Fig. 6D). Furthermore, a supplement of L-serine to the culture medium significantly increased D-serine concentration in pure astrocyte cultures, the same treatment had no effect on D-serine level (Fig. 6D). Furthermore, a supplement of L-serine to the culture medium significantly increased D-serine concentration in pure astrocyte cultures, the same treatment had no effect on D-serine level (Fig. 6D).

To extend the above findings in cell cultures to a more intact preparation, we further examined whether D-serine is also critical for LTP induction in hippocampal slices. To address the question whether endogenous D-serine is also critical for the induction of LTP in hippocampal slices, we directly examined the effect of DAAO on D-serine in hippocampal slices. (Fig. 7). DAAO significantly reduced the magnitude of LTP induced by TBS (Fig. 7C and F). Furthermore, preincubation of slices with DAAO (0.1 units/ml) for 45 min to degrade endogenous D-serine also greatly reduced LTP (Fig. 7D and F). Finally, addition of D-serine (100 μM) to the slices 10 min before the onset of the experiment largely reversed the effect of DAAO preincubation on LTP (Fig. 7E and F). Taken together, these results show that endogenous D-serine is also critical for the induction of LTP in hippocampal slices.

DAAO Suppressed NMDAR EPSCs in Hippocampal Slices. To further test the idea that DAAO inhibits LTP induction in hippocampal slices by suppressing NMDAR activation through the depletion of endogenous D-serine, we directly examined the effect of DAAO on the NMDAR-mediated component of EPSCs. This was done by omitting Mg2+ and adding DNQX (25 μM) in the recording solution. After perfusion of 0.1 units/ml DAAO for >20 min, we found that the NMDAR-EPSCs were significantly suppressed, and this suppression was reversible when DAAO was washed out (Fig. 8, which is published as supporting information on the PNAS web site). In contrast, the same concentration of DAAO did not affect AMPAR-EPSCs that were evoked in the presence of 100 μM APV and 2 mM Mg2+, indicating specific action of DAAO on NMDARs.

D-serine is released from glial terminals but not from neuronal terminals. To address the question whether endogenous D-serine releases from glial cells or neurons in acute brain tissue, we prepared highly purified neuronal terminal synaptosomes and glial terminal GPV (21, 22). We found that treatment of GPV with 0.2 mM glutamate for 5 min increased D-serine in the supernatants of GPV from 3.65 ± 0.77 (control group, n = 4) to 5.05 ± 0.82 nmol/mg protein (n = 4, P < 0.01, compared with control group). In contrast, D-serine in the supernatant of synaptosomes was undetectable, even after being treated with glutamate (0.2 mM, 5 min) or high K+ (120 mM, 5 min).
Discussion

In the present study, we found that correlated pre- and postsynaptic spiking induced LTP in mixed cultures in which neurons were in contact with astrocytes, but not in GCM cultures in which neurons were fed with glial-conditioned media in the absence of astrocyte contact. Astrocytes have been reported to play an important role in synaptogenesis between retinal ganglion cells (7, 8). The failure in LTP induction in GCM cultures we observed is unlikely to be caused by a deficiency in synapse formation, because apparent normal spontaneous and evoked synaptic transmission was found in GCM cultures (Figs. 1 and 4; see also refs. 7 and 8).

Induction of LTP by correlated pre- and postsynaptic activity in both hippocampal slice and cultures depends on Ca\(^{2+}\) influx through NMDARs (17, 39). Full activation of the NMDARs requires the presence of coagonists for its glycine-binding site, e.g., glycine or D-serine (31). We found that antagonists of either NMDARs or their glycine-binding sites blocked LTP induction in hippocampal neurons in mixed cultures and freshly isolated slices (Figs. 2 and 7), consistent with previous reports (17, 32, 39). Furthermore, supplement of D-serine in GCM cultures enabled LTP induction in these neurons (Figs. 3 B and D), suggesting that the failure in LTP induction in these neurons is due to the deficiency of this ligand for the glycine-binding site of NMDARs. This notion is supported by the finding that in GCM cultures, the NMDAR/AMPA ratio of EPSCs was significantly reduced, and supplement of D-serine resulted in a much more pronounced increase in the ratio, as compared with that in mixed cultures (Figs. 5 A and C).

Both glycine and D-serine are effective ligands for the glycine-binding site of NMDA receptors (31, 40). It has been suggested that astrocytes may play a key role in NMDAR function by controlling the extracellular concentration of glycine or D-serine (33, 34, 37, 41, 42). Although cerebrospinal fluid contains relatively high concentration of glycine (31), the synaptically available glycine for the activation of NMDARs may not exist at saturating levels (43, 44), possibly due to the presence of the glycine transporters expressed on astrocytes (42–45). Recent studies suggest that in many brain regions, including hippocampus, D-serine rather than glycine may serve as the endogenous ligand for the glycine-binding site (23, 33–37). In the present study, a significant D-serine level was found in the culture supernatant and in the cell lysates from pure astrocyte cultures, but not from GCM cultures (Fig. 6). Pretreatment of D-serine to promote synthesis of D-serine or acute influx of D-serine resulted in a much more pronounced increase in the level of D-serine in the culture supernatant and in the cell lysates from pure astrocyte cultures (Fig. 7). This finding confirms that endogenous D-serine rather than glycine is critical for LTP induction. This notion is further supported by the finding that DAAO reversibly reduced the NMDAR component of EPSCs in both cultured neurons and hippocampal slices (Figs. 5 and 8; ref. 34). The inhibitory effect of DAAO on NMDAR-EPSCs was found to be more pronounced in mixed cultures than in slices (compare Fig. 5 B and D to Fig. 8). This may be attributed to a more severe diffusion barrier for DAAO in the slice preparation (34). Although DAAO caused only ∼30% suppression in the amplitude of NMDAR-EPSCs in CA1 pyramidal neurons (Fig. 8), it significantly diminished the magnitude of LTP (Fig. 7F), suggesting that high-level activation of NMDARs is normally required for LTP induction.

The potential involvement of glial cells in neuronal plasticity and higher brain functions has long been suggested (10, 12, 15, 16, 46). The present study provides evidence for the involvement of astrocytes in LTP induction and the underlying mechanism. Astrocyte-derived D-serine, by modulating the level of NMDA receptor activation, may regulate the extent of LTP induced by correlated synaptic activity. Because the glutamate released due to synaptic activity may evoke D-serine release through activation of non-NMDA receptors in astrocytes (36), and release from a large population of astrocytes may be triggered through propagated Ca\(^{2+}\) waves (3–5, 18), glia-dependent modulation of synaptic plasticity may serve for long-range cross-talk between activated synapses. The prevalence and the physiological implications of such gliomediated synaptic cross-talk in the processing and storage of information in the neural network remain to be further explored.

We thank Dr. Qian Hu for confocal technical help and Xiao-Yuan Zhu for preparing cell cultures. This work was supported by a grant from the Major State Basic Research Program of China (G2000078900) and by Shanghai Science and Technology Development Foundation.
